A.1 INTRODUCTION

This appendix presents the results of the data evaluation performed to determine the chemicals of potential concern (COPCs) for use in the Galena Baseline Risk Assessment.

COPCs for Galena Baseline Risk Assessment were identified, in general, following guidance in Chapter 5 (Data Evaluation) of the *Risk Assessment Guidance for Superfund, Volume I Human Health Evaluation Manual (Part A)* (USEPA, 1989) and the *Guidance for Data Useability in Risk Assessment* (USEPA, 1992a). COPCs were identified for both organic and inorganic analytes in soils and waters. This was done for each of following evaluated sites for the quantitative risk assessment: Fire Protection Training Area (FPTA), Galena POL (POL_G), and the six source areas of the West Unit—Waste Accumulation Area (WAA), Million Gallon Hill (MGH), Power Plant UST No.49, JP-4 Fillstands, Building 1845, and Building 1700. For the quantitative risk assessment, data were compiled from 1992 through 1994. Soil data were divided into surface and subsurface classifications, and water data were divided into surface water and groundwater.

This appendix is divided into five sections. Section A.2 presents the COPCs identified for Galena Baseline Risk Assessment sites, Section A.3 gives an overview of the technical approach used, and Section A.4 gives detailed results of the analysis performed. Lastly, references are in Section A.5. Attachments to this appendix, located at the back of the appendix, provide data summary tables and the raw data used to determine COPCs.

A.2 SUMMARY

COPCs represent chemicals that are positively identified as present at a site due to historical activities at the site. COPCs include those chemicals that are:

- Measured at levels significantly elevated above levels measured in associated blank samples [i.e., chemicals for which $\geq 5\%$ of the measurements exceeded the upper tolerance limit (UTL) for blanks]; and
- Measured at levels significantly elevated above naturally occurring levels.

COPCs were determined using the statistical approach described in this appendix to focus the data analysis efforts (i.e., risk assessment) on only those compounds that are of concern at the site (i.e., COPCs). Chemicals that were not detected at prescribed concentrations or frequencies were eliminated as possible COPCs. The resulting list of COPCs was then evaluated through these risk assessment related procedures. For example, the COPCs presented in this appendix were further refined by the risk assessors using risk-based screening. The results of the risk-based screen are presented in Appendix B.

Figure 3-2 (see Section 3 in Volume 1) details the decision path used to determine COPCs for the data. COPCs were identified using the principles described in USEPA guidance documents (USEPA, 1989 and USEPA, 1992a). Steps taken to determine COPCs included comparisons of site concentrations to blank concentrations and, for inorganic chemicals, comparisons to background concentrations. Figure 3-2 is different from the historical application of procedures described in the USEPA guidance documents in that:

- Uncensored data were reported by the analytical laboratory in 1992 (just organics), 1993, and 1994, which allowed the use of measured values instead of arbitrary proxy concentrations for results reported as "Not Detected" [this use of measurements as recorded by a lab is the preferred approach over using arbitrary proxy concentrations, according to Gilbert (1987) as referenced in USEPA (1991)];
- "Occurrence" (as used to calculate "frequencies of occurrence" or "frequencies of detection") was defined as a result exceeding the UTL for uncensored blank data as opposed to the normal usage of "occurrence" as "detected" results five times greater than the maximum blank detection (or ten times the maximum blank detection for common laboratory contaminants).

These changes from historical applications allowed a more technically justifiable determination of the COPCs without the potential for bias due to arbitrary limits based on factors of a single measurement (e.g., the 5 times and 10 times rule for evaluating results relative to blank data) or arbitrary data values as proxy concentrations for not detected results (at least for 1992 organics, 1993, and 1994 data). The justification for this approach is provided in this appendix.

Tables A-1A through A-1H give the COPCs for the all of the sites. The COPCs listed in these tables represent chemicals that passed all criteria to be concluded as positively identified at a particular site due to past practices. Additional screening was performed to identify the final COPCs that were quantified in the risk assessment.

A.3 TECHNICAL APPROACH

The technical approach discussed in this section addresses how COPCs were determined and how site data were combined to calculate summary statistics for the risk assessment.

COPCs were identified by a technical approach following the *Risk Assessment Guidance for Superfund Volume I Human Health Evaluation Manual* (USEPA, 1989). The evaluation to determine COPCs for the risk assessment is presented in Figure 3-2 and includes the following steps as outlined in the USEPA guidance:

- Review raw data for representativeness;
- Review blank data;
- Compare site results to blank data;
- Perform comparisons between site and background concentrations for naturally occurring chemicals (i.e., inorganic chemicals);

- Calculate frequency of occurrence for site chemicals; and
- Calculate summary statistics for COPCs.

Each of these steps are described in the following subsections.

A.3.1 Review Raw Data for Representativeness

The first step in the COPC identification process is to review the available raw data for applicability. The USEPA guidance states that all available data should be used to determine COPCs if the data are of sufficient and comparable quality and representative of site conditions. According to USEPA guidance, this data review process must include an evaluation of the following areas:

- Data available from historical site investigations;
- Analytical methods;
- Quantitation limits; and
- Data qualifiers.

Each of these steps in the data review process are addressed below.

A.3.1.1 Review of Data Available from the Site Investigation

A substantial number of samples have been collected at Galena Airport between 1992 and 1994. Many of these samples were collected in order to characterize the sites for a risk assessment. USEPA guidance allows the compilation of data from different sampling events as long as several criteria are met. These criteria are:

1. if sampling methods were similar;
2. if analytical methods were similar;
3. if Quality Assurance/Quality Control (QA/QC) procedures and criteria were similar;
4. if concentrations were similar (i.e., significant changes did not occur to the site between sampling events).

These criteria were met for all data where samples were collected in support of the risk assessment. However, this does not mean that data from all the samples ever collected were used in this risk assessment.

Data for each site were reviewed to ensure that only data appropriate for a risk assessment were used to identify COPCs. Often measurements were made for the same analyte by more than one method. This occurred when a few samples were originally analyzed by a less exact or less sensitive (i.e., less costly) method to screen larger areas of a site. Then either at the same time or at a later sampling event, samples were analyzed by a more exact or more sensitive method to provide data of a sufficient quality for a risk assessment.

For this risk assessment, data were compiled from all sampling events at Galena Airport and reviewed for appropriateness for a risk assessment. Appropriate data were retained for the COPC determination process. Appropriate data were defined as:

1. Results from samples that provided the best characterization of the site in terms of coverage (i.e., samples that covered the site and provided a characterization of the site contamination); and
2. Results from analytical methods that provided the most sensitive detection capabilities along with the most accurate identification of the target analyte.

"Inappropriate" data were still used to qualitatively confirm the presence or absence of target analytes. This way the best quantitative data with the highest accuracy of analyte identification were used to assess risk.

For example, some samples from an event were taken to determine the extent of a plume or the presence of contamination and were found to be "clean". Measurements from such samples can "dilute" the estimated amount of contamination present at that overall area. To avoid underestimating contamination, data associated with clean samples for organic analytes (not inorganics or pesticides) from several locations were not used quantitatively in the risk assessment process. Table A-2 presents the site, matrix, and location where samples were considered clean and, thus, not used to characterize contamination at a site.

Table A-2
Locations Where Organic Data Were Considered Clean and Not Used

Site	Matrix	Location
West Unit	Subsurface Soil	09-MW-02-02 09-MW-03-02
	Groundwater	11-MW-01
FTA	Groundwater	01-MW-03
POL_G	Groundwater	05-MW-08 05-MW-09

Another step taken to ensure only data appropriate for a risk assessment were used to identify COPCs was checking data for chemicals analyzed by several methods. For example, groundwater was sampled in 1992 and 1993, and samples were analyzed by SW8010, SW8020, and SW8015. Another round of groundwater sampling was conducted in 1994 and samples were analyzed by SW8260, a GC-MS method. While SW8260 provides a similar detection capability to SW8010, SW8020, and SW8015, it surpasses these methods by the positive MS identification of the analyte. Also samples collected in 1994 provided the

best coverage of the site and allowed for a single "snapshot in time" representation of the site. Therefore, this method/year combination was viewed as providing the preferred data which was specifically designed for the risk assessment (not necessarily for all project objectives, but for just the risk assessment).

A review of the SW8010, SW8020, and SW8015 methods and data indicated that it was not reasonable to combine these data with the SW8260 data. The GC analytical methods are different and are more variable (in terms of relative imprecision) than the GC-MS method. Therefore, it was decided to use only the SW8260 groundwater data from 1994 to characterize the groundwater for a risk assessment, except for the analytes ethanol and ethyl ether which are not included in SW8260. The data for ethanol and ethyl ether came from the SW8015 data. A list of analytes from the 1992 and 1993 data was compared to the list of analytes detected in 1994 to ensure no analytes were falsely excluded. All analytes detected in 1992 and 1993 were also detected in 1994. Quantitative differences in sample results, by year and/or by method, were not used to identify the most appropriate data for the risk assessment. Thus, Radian feels the approach used to determine which data collected were appropriate for a risk assessment is justified and guarantees the most accurate assessment of risk at sites on Galena Airport. Table A-3 presents the preferred analytical methods chosen for analytes where data were available from multiple methods.

Table A-3
Preferred Methods for Analytes with Results by Multiple Methods

Matrix	Situation	Sampling Year			Preferred (used for Risk Assessment)
		1992	1993	1994	
Groundwater, Surface Water	Sites with 1994 sampling event	8010/8015/8020		8260	8260
	Sites without 1994 sampling event	8010/8015/8020		NONE	8010 for Ethanol, Ethyl ether 8020 for BTEX 8015 otherwise

A.3.1.2 Analytical Methods

An examination of the analytical methods used to evaluate the data for the investigations was an important part of the data review process. It focused on ensuring that the analytical methods used were appropriate for the analytes of interest (for example, chemicals known to have been used at the sites). For each of the three investigations, the approved sampling and analysis plans were implemented successfully and data were generated using the planned analytical methods. More information about the analytical methods can be found in the QA/QC Summary Reports, such as the January 1995 QA/QC Summary Report: Quality Assurance Kalakaket Creek Radio Relay Station and Galena Airport (USAF 1995a).

A.3.1.3 Quantitation Limits

The third step in the data review, as specified in the USEPA guidance, involves the evaluation of "quantitation limits" for all of the chemicals assessed at the site. All laboratory analyses met the sensitivity requirements of the QA plan. Additionally, data were available for 1994 below these limits, which improved the project's ability to make decisions about the presence or absence of chemicals at the site.

One historical problem with making decisions from analytical data has been values reported as "not detected," causing either the elimination of certain chemicals from further consideration (because they are believed to be absent from the site) or the use of proxy concentrations in place of nondetects, which potentially cause incorrect decisions. Sample-specific method detection limits (MDLs) were available for assessment of the data, but they were not used by the analytical laboratory to censor data during 1992 (for organics only), 1993, and 1994. These "uncensored" data were requested from the laboratories for all sample and blank results. Uncensored data are measurements for which the results are reported "as measured" by the analytical instrument. The results are obtained using standard analytical and data reporting techniques, except that results below the MDL are not discarded

or reported as "not detected." Thus, numerical results are available for a larger proportion of the sample measurements. "Censoring," while often used for a variety of reporting needs (e.g., censoring all results below a health-based criteria and reporting "< Health Limit"), complicates statistical analysis and interpretation by removing information about measurement variability. Censoring also necessitates the use of proxy concentrations for results reported as "not detected" so that a numerical estimate is available for each result. A better approach is to use the uncensored data generated by the analytical laboratory and prevent the need for proxy concentrations (USEPA, 1992a and Gilbert, 1987). While these measurements below the MDL may not indicate the presence and/or concentration of target analytes as reliably as measurements above the reporting limit, the uncensored measurement is a better estimate of the concentration than any proxy concentration and will allow a better characterization of site conditions by data users and decision makers.

Uncensored data were used as reported for much of the inorganic and organic analyses. This includes the use of negative results when they were reported for inorganic constituents. The use of negative results is appropriate and justifiable and has been recommended by numerous authorities for this type of application. The use of negative measurements is technically appropriate for all methods but is more common for inorganic methods. As the true concentration approaches zero, measurement variability causes the range of possible measurements to include negative results. Exclusion or censoring of these negative measurements would bias any summary statistics (e.g., the average or mean) and thus provide a biased estimate of site conditions. Therefore, all uncensored measurements (i.e., positive and negative) were used as reported in the statistical determination of COPCs.

For some of the organic and inorganic analytes, the data are automatically censored by the laboratory even when uncensored data are requested. This happens for those methods that use electronic filtering mechanisms to eliminate signals below a specified threshold (e.g., peak height, peak width, area reject). Thus, for these methods, results included data that were above the quantitation limit, "J" flagged data (reported results less than a quantitation limit), and "NDs" (where an "ND" indicated "no signal greater than the

established threshold", not that the measurement was less than a reporting limit). Because there is usually a positive concentration related to the signal threshold (i.e., ND does not mean zero concentration), proxy concentrations were estimated for uncensored data reported as "NDs".

There are a number of ways for estimating proxy concentrations (e.g., substituting one-half the detection limit, substituting a uniform random number between zero and the reporting limit, etc.). The data had J-flagged results (i.e., results lower than the reporting limit); thus, using a number between 0 and the MDL would provide an overly conservative estimate of NDs since it is known that the instrument can detect results down to the minimum J-flagged result. Proxy values were therefore estimated for NDs using a uniform random number between 0 and the smaller of the minimum result or the MDL for each site and media. This is believed to be the best approach, since the MDLs were, in some cases, orders of magnitude higher than the maximum detected results. In these cases, using a number between 0 and the MDL would result in means and UCLs that were higher than the maximum detected result for some sites and media.

The approach used for estimating NDs is consistent with the USEPA *Risk Assessment Guidance* document (RAGS) (USEPA, 1989). RAGS states that if using one-half the MDL for NDs results in UCLs that are larger than the maximum detected result, then the ND records can be eliminated from the data set. The ND records were not eliminated, but rather the ND record was replaced with a more reasonable proxy concentration (i.e., a random number between 0 and the smaller of the minimum detected result or the MDL, instead of one-half the MDL).

A.3.1.4 Data Qualifiers or Codes

The fourth step in the data review process involves a review of data qualifiers or codes reported with the analytical results so that uncertainties can be identified and evaluated. All data that were validated during the QA/QC process were used to determine

COPCs. This includes some data with qualifiers that indicate known identities, but uncertain concentrations. A complete description of the laboratory qualifier codes associated with the analytical data is included in each analytical report on the page of flag definitions.

A.3.2 Review of Blank Data

According to USEPA guidance, the second step in determining COPCs is to review the blank data to determine if site results are due to a source other than historical site activities (e.g., sampling or laboratory contamination). Ambient, equipment, method, and trip blanks are included in the analytical program to provide an indication of the potential introduction of contaminants into samples during sample collection or analyses (e.g., during sampling, decontamination, or shipping). USEPA guidance (both Contract Laboratory Program and risk assessment guidance) suggests that any site sample concentration greater than 5 times (5x) the maximum blank result for that analyte be considered a positive identification and should be included in the risk assessment. For common laboratory contaminants (CLCs), such as acetone, methyl ethyl ketone, methylene chloride, toluene, and the phthalate esters, the USEPA recommendation is that site concentrations greater than 10 times (10x) the maximum blank result be considered a positive identification and should be included in the risk assessment. The approach used for this analysis to determine positive occurrences or frequencies of occurrence deviates from that suggested in the USEPA guidance.

Blank results can be used to evaluate the "noise" in the analytical system to verify whether site concentrations were in fact greater than the analytical noise. For this program, blank results were used to establish UTLs for each year of sampling. UTLs are an estimate of an upper extreme of possible measurement results due to analytical noise (i.e., when there is not site contribution of the target analyte). A site result greater than the UTL for the blanks for the appropriate year was considered a positive occurrence for that chemical. This approach is a more justified approach than applying the arbitrary 5x/10x approach in that it is a more accurate assessment of the likelihood of a measurement to be

sampling and analytical noise or true contamination on-site. The intent of the 5x/10x rule in the USEPA guidance is to identify results that can be distinguished from analytical noise and those that cannot. The calculated UTLs for blank results accomplish this objective better than using the arbitrary 5x/10x limit because they are probabilistic upper limits based on the number of samples (i.e., blanks) available to characterize the system and a desired confidence to establish a limit for this system. The process used to establish UTLs is presented next. More details about the advantages of UTLs compared to the 5x/10x rule are in Attachment A-1.

Before calculating UTLs, the blank data for each year were evaluated to determine if there were any extremely high or outlying data which would indicate unusual events. Box plots of the data were generated for each matrix (waters and soils) and analyte for the different types of blank data for each sampling year. Sampling years were segregated because there were potential differences in both the sampling and analytical processes each year that might change the potential for sampling or analysis contamination. Box plots are useful graphical tools for comparing the central tendency and dispersion of data distributions. An example of the box plot figures used for this analysis is presented in Figure A-1. Figure A-1 shows an example figure with the box plots for two cases:

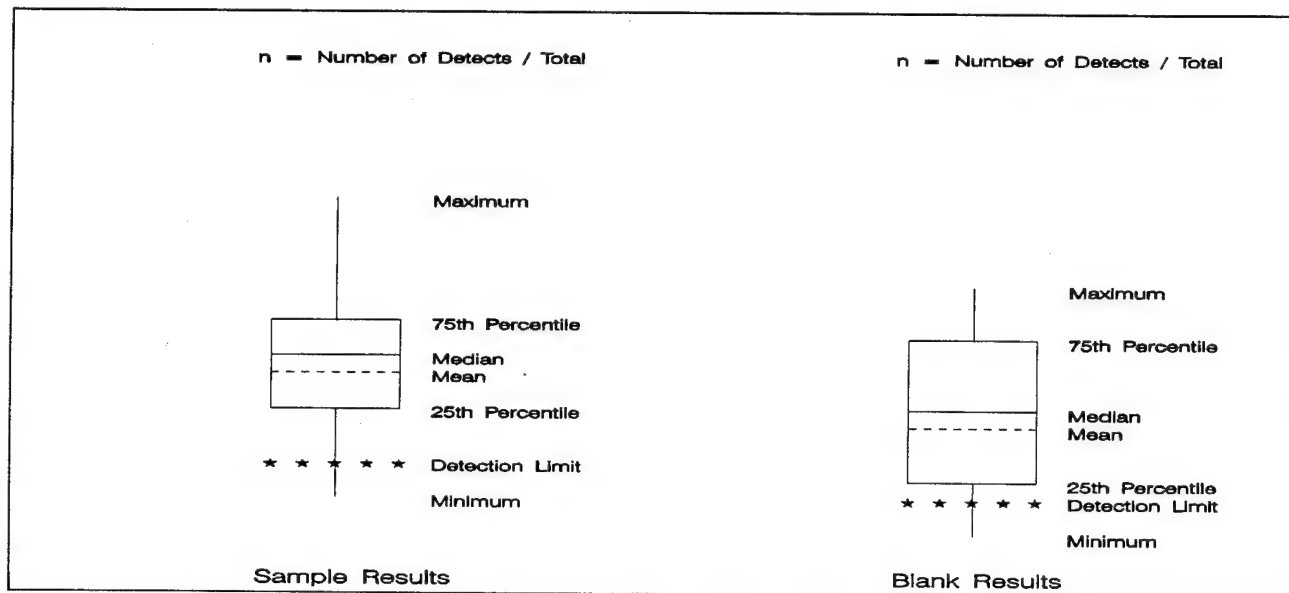

- 1) Where the field sampling (source) data are indistinguishable from blank data; and
- 2) Where the source data appear different from blank data.

Each box plot is annotated to describe the summary statistics shown in the plot. The bottom and top of the box are the 25th and 75th percentiles of the data, respectively; the bottom and the top of the vertical lines extending from the box plot are the minimum and maximum of the data, respectively; the solid horizontal line contained within the box is the median (the 50th percentile); and the dashed horizontal line is the mean. The labels on the x-axis identify the type of sample (e.g., sample results or blank results). The sample size is also identified

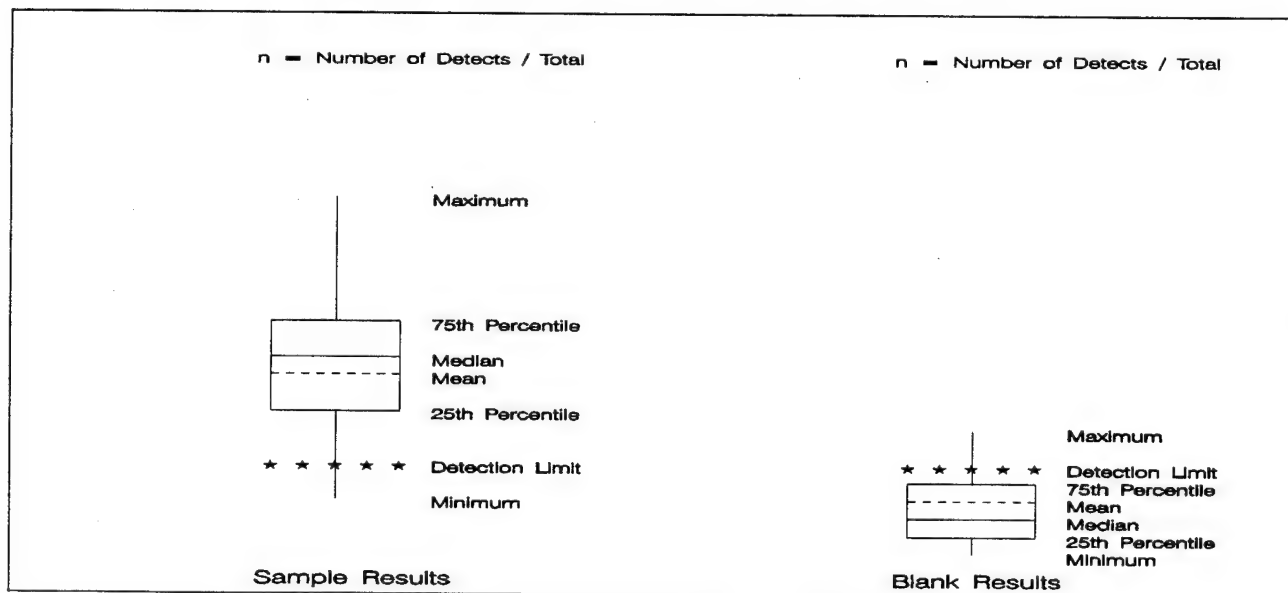

Figure A-1

Example Box Plots

Where Samples are Not Distinguishable from Blanks

Where Samples are Distinguishable from Blanks

at the top of each box plot. Lastly, horizontal stars indicating the median method detection limit are overlaid on the box plots.

Reviewing the box plots showed that, in general, there were no apparent differences between the distributions of blank results for the different types of blank samples (i.e., field and laboratory), for a given analyte in a given year. The different types of blank samples that were most representative of conditions were therefore pooled for each matrix, analyte, and year. Values that were statistical outliers or that were judged during the QA/QC evaluation to be potentially biased high were flagged, but included in the calculation of the UTLs for blanks.

Upper tolerance limits for the blank results were calculated assuming a normal distribution for those blank data sets found to be normally distributed according to the Shapiro-Wilk test (Gilbert, 1987). The normal UTL is calculated using the following equation:

$$UTL = \bar{x} + (K \times s)$$

where \bar{x} is the estimated sample mean, K is the tolerance factor, and s is the estimated standard deviation. Normal UTLs were calculated for a coverage of 95% (i.e., the 95th percentile) with 95% confidence. Censored data were reported for some of the organic analytes. For these organics, values reported as ND were estimated by using probability plotting methods for data that were normally distributed (Gilbert, 1987) or random uniform numbers between 0 and the MDL for data that were not normally distributed. For blank data sets that were not normally distributed, non-parametric UTLs were calculated. The non-parametric UTL is simply the maximum blank concentration. However, the coverage for non-parametric UTLs is a function of the sample size and was often less than the coverage of 95% used for the normal UTLs. The next section discusses how the blank UTLs were used in the comparison to site data.

A.3.3 Frequencies of Occurrence for Site Data

The third step in the COPC determination process was to compare the site data to the blank data to determine the potential for false-positive measurements because of laboratory or field contamination and to determine if target analytes occur frequently enough to be retained as a COPC. Frequencies of occurrence were calculated for each analyte, where a positive occurrence was any result greater than the UTL for the blanks. According to USEPA guidance (USEPA, 1989), analytes may be considered as candidates for elimination from a quantitative risk assessment if they are infrequently detected and there is reason to believe the detection is not due to site operations or disposal practices. For this analysis a detection frequency limit of five percent (5%) was used. Analytes with positive occurrences less than five percent were considered separately based on detected results and applicable screening levels. Analytes with a frequency of occurrence greater than or equal to 5% for any site were retained as a possible COPC in the risk assessment. Inorganic analytes were further evaluated by comparing site results to background concentrations, as discussed in the next section.

A.3.4 Comparison of Inorganic Site Concentrations to Naturally Occurring Background Levels

The fourth step in the COPC determination process was to compare site results to background levels for naturally occurring chemicals.

A statistical "means comparison" was performed between site and background concentrations to determine if there was any evidence of metals contamination on the site. In addition, an "individuals comparison" was performed to determine the potential for a hot spot. In Section A.3.4.1, a summarization of the background data that were used for these comparisons is given and Section A.3.4.2 gives an overview of these two types of tests.

A.3.4.1 Characterization of Background Data

"Background" concentrations for soil and water metals represent metals concentrations that are indigenous to Galena, Alaska. Background concentrations were characterized for surface water, groundwater, and soils. Background soils, ranging from depths of 0 to 7 feet, were divided into surface soils (from 0 to 2 feet) and subsurface soils (from below 2 feet). All background data collected has been used for the background comparisons.

A.3.4.2 Means and Individuals Comparisons of Inorganic Site Concentrations to Background

Two types of statistical analyses were used to compare inorganic results from site areas to background areas. Tests of central tendency (e.g., means comparisons) were used to determine if, on the average, concentrations of metals in the source areas were greater than average background concentrations. The results of the tests of central tendency were used to determine whether or not a particular inorganic chemical should be included as a COPC. In addition, individual source area results were compared to UTLs for background. These comparisons were used to determine if individual sample results indicated the presence of hot spots.

A discussion of the applicability of tests of individual comparisons and tests of central tendency (e.g., means comparisons) is given in the first subsection below. The second subsection below gives a discussion of the statistical methods used to perform the means and individuals comparisons. Results of these statistical comparisons are provided in Section A.4 of this appendix.

Description of Tests of Means and Individuals Comparisons

Two types of statistical comparisons may be used to compare results from different sample populations. Means comparisons may be used to compare the average background concentration to a corresponding average concentration for a site of interest (e.g., downgradient monitoring wells). Additionally, individual results from each of the wells may be compared to calculated UTLs for background concentrations.

Means comparisons [e.g., the Student's t-Test, the Wilcoxon Test, Analysis of Variance (ANOVAs)] are the preferred approach to testing whether or not measurement results indicate a difference between two or more "sample populations" of interest. In this risk assessment, as in other similar studies, the two sample populations are "background" and "site." Since these statistical concepts are more readily understood with examples, the following discussion will use the comparisons for groundwater as an example assessment to which these concepts may be applied. Conceptually, a means comparison tests the measurement results to determine the likelihood that they actually came from a single parent population, rather than from two different populations. (A Student's t-Test is a statistical test that can be performed when comparing two sample populations. An ANOVA is a statistical test that can be performed when comparing multiple sample populations). It is assumed that there is no difference between the two populations (i.e., that downgradient is not different from background) as long as the observed difference between their averages is within the range that could be attributed to chance.

The amount of difference attributable to chance in a means comparison is a function of variability in the sample data and the number of sample results available. The difference attributable to chance reflects the uncertainty in the statistical test and becomes smaller as the sample size increases. It also becomes smaller as the variability among results within each of the two populations decreases. The uncertainty resulting from sample size and variability directly affects what is known as the *power* of the statistical comparison. The power of a statistical comparison is the probability of detecting a given difference at a

specified confidence level. As the power increases, it becomes possible to detect smaller and smaller differences between the true population means. Thus, with increased power there is less risk of failing to detect a difference that actually exists. This should not be confused with the confidence level of the test, which is related to the probability of erroneously concluding that a difference exists between the population means, when in fact the population means are not different. (As the confidence level increases, the probability of incorrectly indicating a difference decreases.)

The comparison of individual results to UTLs of a given population is another way of testing the difference between two sample populations. The UTL used in these comparisons represents an estimate of the upper 95th percentile (i.e., a coverage of 95%) with 95% confidence of the true background concentration of the analyte of interest. For data that are not normally distributed, the coverage may be $\leq 95\%$ (a 95% coverage may not be achievable given the limitation of the statistical methods used for the non-normal case) and the confidence level is 95 percent. Thus, there is a relatively small chance, on the order of 1 in 20, of a sample of uncontaminated groundwater (i.e., groundwater that is no different from background) having a metal concentration greater than the UTL. When individual sample results are compared to UTLs, they are interpreted to indicate the presence of contamination when they exceed the UTLs. On the other hand, samples are considered to be not different from background as long as they do not exceed the UTL.

In most cases, means comparisons offer significant advantages over comparisons using individual results compared to UTLs. However, both types of comparisons are useful and they provide different information about the data and the parent populations. Means comparisons offer greater statistical power than comparisons based on the UTL. Thus, means comparisons can detect smaller differences between two populations and are less likely to fail to detect a difference that actually exists. Used to compare monitoring well results to background data, means comparisons can detect lower levels of contamination and are less likely to fail to detect contamination when it actually exists. Comparisons using individual results compared to UTLs are less sensitive and more likely to

fail to detect contamination because of the inherent uncertainty in individual measurements. Much of this uncertainty is attributable to random measurement error, which is effectively "averaged out" in means comparisons where multiple results are considered together as a set.

The strength of means comparisons can also be their weakness. In the same way that random measurement error gets averaged out in the calculation of a sample mean, actual, non-random effects can be diluted and overlooked. For example, four wells might be grouped together based on available hydrogeologic information. Whereas comparing average results for the four wells offers more power, it is important not to overlook cases in which results from one member of the initial group stand out as appreciably different from the others. When this occurs, comparison of this single anomalous result to the UTL offers an approach for evaluating it separately, and, for example, deciding if the initial well grouping should be reconsidered. Comparisons based on the UTL are also useful when there is only one result available for comparison. However, if a conclusion is drawn that a downgradient well is not different from background based on a single downgradient result, it must be acknowledged that there is a significant risk that there actually is a difference that was not detected simply because of the paucity of downgradient data.

Statistical Methods

As discussed in the previous section, tests of central tendency provide a good indication of whether or not the overall distribution of site concentrations and background concentrations differ significantly. Thus, results from the tests of central tendency were used to determine whether or not an inorganic was a possible COPC. Results from the individual comparisons were used to provide additional information about the site and to help in evaluating the power of the test. Tests of central tendency and individuals comparisons are performed to answer two different questions, and thus the results of the two tests may differ. For example, the means comparison may show that there is no statistically significant difference between the site and background soil concentrations, on the average, while there may be one or two individual results that are greater than the UTL for background. This

may indicate that, as a whole, the site is not different from background, but that there may be localized hot spots on the site. In such a case, further subdivisions of the area may be considered.

For the soil and water data, the site and background data sets were evaluated with the Shapiro-Wilk test (Shapiro and Wilk, 1965) to determine if the data sets were normally distributed. Conclusions of the Shapiro-Wilk test were used to determine an appropriate method for comparing potential source area results to background results. An alpha level of 0.05 was used to determine significance for the test of normality. The parametric Student's t-test (Proc t-test, SAS/Stat, 1989) was used to compare central tendencies (i.e., compare means) if results of both site and background data sets were normally distributed. The non-parametric Wilcoxon Rank-sum Test (Proc npar1way, SAS/Stat, 1989) was used to compare central tendencies if results of either site or background data sets were not normally distributed. The latter test compares the central tendency of the distributions of results by comparing the rank mean value for the site to the background rank mean value. This is obtained by first combining the source area and background data sets for an analyte. The complete set of concentrations are then ordered. The rank of a value is its position in the combined data set (lowest = 1, second lowest = 2, etc.). The average rank for the values corresponding to the background data can then be compared to the average rank for the site. If the second is measurably larger than the first according to the non-parametric test, then one would conclude that concentrations tend to be higher on the site than in the background area. Thus, the comparison can be made of the ranks of the data, and it is not necessary for the background and site results to follow the same distribution (as is the case for parametric procedures). An alpha level of 0.20 was used to determine significance for all tests of central tendency. This value is recommended in the *Guidance for Data Useability in Risk Assessment* (USEPA, 1992a). Individual results from the sites were compared to the UTLs that were calculated using the appropriate parametric or non-parametric method as described earlier for blank data. This approach is drawn from USEPA's RCRA (1992b) guidance for statistical analyses in groundwater monitoring and is applicable to the situation described in this appendix.

An analyte is considered a possible COPC if it had the following properties. First, the analyte must have at least one result greater than the blank UTL, during the blank comparison. Second, the analyte must have a site average significantly greater than the background average, for the background comparison. Third, and finally, the analyte must have at least 5% of its data for a site and matrix greater than the blank UTL. For analytes that are retained as possible COPCs, summary statistics for that analyte, site, and matrix are calculated.

A.3.5 Calculate Summary Statistics for COPCs

The next step in the data analysis was to calculate summary statistics for those analytes determined to be possible COPCs. Measurements for non-detect results were estimated by substituting uniform random numbers between 0 and the smaller of the minimum result or the sample specific method detection limit for each site and for each matrix, analytical method, and analyte. Average site concentrations and the 95% upper confidence limit (UCL) for the average were calculated for COPCs for each site. The UCL was calculated following the Supplemental Guidance to RAGS (USEPA, 1992c). Before calculating the 95% UCL, each set of results (by matrix, analytical method, and analyte) was tested with the Shapiro-Wilk test to determine whether the data set had a normal distribution, a log-normal distribution, or had neither distribution. Using the appropriate distribution, the 95% UCL was then calculated. For data that had neither distribution, a normal UCL was calculated. These summary statistics were used by the risk assessors to perform further screening of the COPCs as well as conduct risk assessments.

A.4 RESULTS

This section presents the results of the data analyses performed to determine COPCs for the risk-based screen and the risk assessment. Results are presented for each of the following steps in the COPC determination process:

- Review blank data and determine UTLs for blanks separately for each year of sampling;
- Compare site results to appropriate sampling year's blank data, and calculate a combined frequency of occurrence for site chemicals for all of the data;
- Perform comparisons between site and background concentrations for naturally occurring chemicals (i.e., inorganic chemicals) for all of the data.

Additionally, the summary statistics calculated for contaminants of potential concern are presented.

A.4.1 Review of Blank Data

The QA/QC Summary reports for the respective years of sampling contain a discussion of the validity of the blank results and associated site results. Blank data that identified blank conditions (i.e., results from validated analyses) were used to estimate UTLs to represent the upper limit of measurements expected for the blank population. Site results greater than the blank UTLs were concluded to indicate potential site contamination. Results less than the blank UTLs were concluded to be potentially analytical system noise and not indicative of site contamination.

A.4.2 Frequencies of Occurrence for Site Data

For each sampling year, the UTL for blanks for every analyte was calculated for soil and water. The frequency of occurrence was then calculated for each analyte, site, and matrix. These results are given in Attachments A-2 and A-3. Attachment A-2 gives results for the groundwater and surface water conclusions for each site. Attachment A-3 gives results for the surface soil and subsurface soil conclusions for each site. In addition to the blank UTLs and the calculated frequencies of occurrence, these tables show the number of samples collected from each site and the range of site results (minimum and maximum).

The tables also show whether or not the chemical was included as a possible COPC and a footnote describing the reason a chemical was or was not listed as a possible COPC.

A.4.3 Comparison of Inorganic Site Concentrations to Naturally Occurring Background Levels

As discussed in Section A.3.4, the fourth step in the COPC determination process was to compare concentrations of naturally occurring chemicals to background concentrations to determine if there is any evidence of metals contamination on the site. Section A.4.3.1 below, discusses tables of the background data that were used for these comparisons and Section A.4.3.2 gives the results of these comparisons.

A.4.3.1 Characterization of Background Data

Tables A-4 and A-5 give summary statistics (e.g., minimum, maximum, mean) for the water (groundwater and surface water) and soils (surface and subsurface) background data, respectively, for each metal. In addition to summary statistics, these tables show the number of samples collected and give information on the UTLs that were calculated for background. [The UTLs for background should not be confused with the UTLs for blanks. Although both sets of UTLs were calculated using the same methods, they represent different things. The blank UTL was used to determine which site results were different from analytical noise. The background UTL was used to determine which individual site results were different from background concentrations.] The type of UTL calculated (normal, lognormal, or non-parametric), and the coverage for the UTL is also given in the tables.

Tables A-4 and A-5 present only those metals used for the comparisons with the site data in this report. More information about background metals data can be found in Section 2 of the *Remedial Investigation Report* (USAF, 1995b).

A.4.3.2 Means and Individuals Comparisons of Inorganic Site Concentrations to Background

Tables with the results of the means and individuals comparisons for waters and soils are given in Attachments A-2 and A-3. Table 1-2 in Attachment A-2 and Table 2-2 in Attachment A-3 provide results for the waters and soils, respectively. These tables show the p-values (i.e., the probability that the two means come from the same parent population) for the tests of central tendency, the conclusion (S = statistically significant at the 0.20 level, NS = not statistically significant at the 0.20 level), the power of the test, and the type of statistical test performed (i.e., Student's t-Test or Wilcoxon test). The power of the test represents the probability of detecting a difference of 40% between the background mean and the site mean at the 80% confidence level. These criteria are recommended in the *Guidance for Data Useability in Risk Assessment* (USEPA 1992a). They also show the background UTLs and the number of site results exceeding the UTLs. The last two columns of these tables indicate whether or not each analyte was listed as a possible COPC and a reason for this conclusion.

A.4.4 Calculate Summary Statistics for COPCs

The next step in the data analysis was to calculate summary statistics for those analytes retained as possible COPCs throughout this process. Organic analytes that had a frequency of occurrence that was greater than 5% for a given site were initially identified as possible COPCs. Inorganic analytes that had a frequency of occurrence greater than 5% and had average concentrations that were significantly greater than background were also initially identified as possible COPCs.

The following summary statistics were calculated for all analytes that were determined to be possible COPCs: minimum, maximum, mean, and 95% UCL for the mean. For censored data, proxy concentrations were estimated for values reported as ND by

substituting a random uniform number between zero and the smaller of the minimum result or the MDL.

Table 1-3 in Attachment A-2 and Table 2-3 in Attachment A-3 give summary statistics for COPCs for waters (groundwater and surface water) and soils (surface and subsurface soils), respectively.

A.4.5 Raw Data

Raw data tables are provided in Attachments A-4, A-5, A-6, and A-7 for surface water, groundwater, surface soil, and subsurface soil, respectively. These tables provide the data source, the lab sample id, the analytical method, the estimated concentration (measured value or proxy value if ND), and the MDL for that measurement.

Attachment 1:

Discussion on Blank Comparisons

1.0 INTRODUCTION

Samples are collected in an environmental investigation to characterize two major populations: a particular site (i.e., geographic region) and an analytical measurement system used to analyze samples from a site (i.e., field and laboratory processes). Commonly, these samples are called "site samples" and "QC samples". Chemical analyses of site samples characterize chemical concentrations in a given medium at a site. Chemical analyses of QC samples characterize the potential for false-positive or false-negative measurements due to activities associated with collecting, transporting, storing or analyzing a site sample. Results of the QC samples are often reviewed to determine if the analytical systems were capable of generating site results that represent a valid characterization of the site, but are also often used to determine WHICH site sample results truly indicate the presence of contamination. This white paper presents an alternate approach to USEPA's published 5x/10x rule for determining which site-sample results are greater than analytical system (field and laboratory aspects) "noise" (where noise can be random noise in an measurement process or contamination due to some field or laboratory source). This alternate approach statistically establishes an upper tolerance limit for the blank population which is then used as the criterion to decide if site-sample results are due to analytical system noise or the presence of a chemical at a site. This alternate approach is proposed because the published 5x/10x rule is arbitrary, does not take into account the amount of information available describing system noise and it can lead to the false conclusion of the presence or absence of potential chemicals of concern at the site.

This white paper outlines the conceptual need for a rule for determining if results of site samples indicate the presence or absence of a chemical; the conceptual basis for the 5x/10x rule as published by USEPA and its associated limitations; the conceptual basis and advantages of the proposed, alternate approach; and a detailed strategy for implementing the alternate approach.

2.0 CONCEPTS

This section of the white paper presents the concepts behind using QC data to determine if results of site samples indicate the presence of potential site contamination; the conceptual basis for the 5x/10x rule and limitations as currently published; and the conceptual basis and benefits of the proposed use of upper tolerance limits for blank data.

2.1 Need for a Rule to Discriminate System Noise from Potential Site Contamination

Samples are collected from environmental sites to determine if past activities have contaminated the site. These samples are collected by field crews using a variety of collection equipment, shipped to analytical laboratories, potentially stored until sample preparation or analysis can occur and analyzed via specified methods for target analytes. An unknown and variable amount of noise is present in each instrumental analysis due to each sample handling step and the instrumental analysis itself. The random component of this noise is seen in the measurements as electronic noise and method detection limits are an attempt to define an upper limit to this noise. Additionally, there is a non-random component often called field or laboratory contamination that causes a bias in measurements. Before an investigator concludes a target analyte is present in a sample and indicates the potential for site contamination, it must be determined if the measured concentration of a target analyte in a sample is due to the random and non-random components of analytical system noise or the combination of this noise and the presence of target analyte due to past site activities. Blank QC samples are analyzed to measure the system noise and to determine how much of a particular site sample result might be due to this noise.

2.2 Conceptual Basis for the Published 5x/10x Rule and Limitations

USEPA has recognized the need for discriminating between site results that are potentially system noise and those that potentially indicate site contamination. While

published as part of several investigation programs, this white paper will focus on this need as relates to a risk assessment.

The Risk Assessment Guidance for Superfund (RAGS) supports the use of blank data to separate analytical noise from contamination during a risk assessment. RAGS provides one method for segregating analytical noise from potential site contamination, the 5x/10x approach. RAGS (Section 5.8, p.5-20) states that one of the criteria for considering an analyte as a chemical of potential concern (COPC) is that it must be detected at levels significantly elevated above levels of the same chemical detected in associated blank samples. RAGS provides the following guidance (the 5x/10x approach) for determining whether a chemical is detected significantly higher than blanks. For "blanks containing chemicals that are not common laboratory contaminants" (Section 5.5, p. 5-17):

"...if the blank contains detectable levels of one or more organic or inorganic chemicals that are not considered by USEPA to be common laboratory contaminants...then consider site sample results as positive only if the concentration of the chemical in the site sample exceeds five times the maximum amount detected in any blank....If all samples contain levels of a target compound list (TCL) chemical that are less than five times the level of contamination noted in the blanks, then completely eliminate that chemical from the set of sample results."

A similar approach is also applied to common laboratory contaminants, except that the factor is 10 times the maximum instead of five times.

The intent of this 5x/10x rule in the USEPA guidance is to identify results that can be distinguished from analytical noise and those that cannot, which will be used to determine chemicals of potential concern (COPC). The purpose of this approach for blank comparisons is valid, however, it can not assess the how likely a measurement is due to analytical noise or representative of site conditions. It arbitrarily establishes a fixed criterion

of 5x or 10x the maximum blank concentration measured, no matter if that value represents a reasonable cut-off point between analytical noise and actual site conditions. The 5x/10x rule has no test for outliers (i.e., blank measurements due to an assignable cause which should be corrected), causing areas that are truly contaminated to be possibly excluded when they should not have been, just because the cut-off criteria were so large. Additionally, it does not consider the amount of blank data available for establishing the cut-off criteria so that the criteria may be set well below concentrations that might truly be expected from the analytical system alone. This can cause site results which are due solely to system noise to be considered potential site contamination and cause unnecessary investigation and/or remediation. Thus, the 5x/10x rule is neither conservative nor an accurate indication of whether a site result is system noise or potential site contamination. A more accurate indicator is an upper tolerance limit on the blank data.

2.3 Conceptual Basis for Estimating an Upper Tolerance Limit (UTL) for Blank Data

To avoid the inaccuracies and potentially serious problems of the 5x/10x approach, an approach using blank UTLs is proposed. That is, a result is not counted as an indicator of potential site contamination (i.e., is significantly greater than blanks) unless it is above the blank UTL. An UTL is a statistical estimate of a percentile of a population made with a specified confidence. Commonly, the 95th percentile of a population is estimated with 95% confidence, which means that 95% of all individual values in a population are expected to be below this UTL. And, we are 95% confident that the true 95th percentile is less than or equal to this UTL. Colloquially, this UTL is often called the 95,95 UTL. Similarly, one could estimate a UTL for the 99th percentile with 95% (or any other desired) confidence.

UTLs are estimated similarly to upper confidence limits (UCLs) (and are often confused with UCLs) by multiplying a factor by a measure of variability (usually the standard deviation) and adding this value to some measure of central tendency (e.g., average

or mean, median). For example, an UTL for blank data that are normally distributed, is derived by the following equation:

$$UTL = \bar{x} + (K \times s)$$

where \bar{x} is the estimated sample mean, K is the tolerance factor, and s is the estimated standard deviation. The K factor is chosen to provide for a coverage (e.g., 95% or the 95th percentile) and a confidence (e.g., 95% confidence). K factors for normal and other distributions are available in a variety of statistical texts. For blank data sets that are not normally distributed, non-parametric UTLs would be calculated. The non-parametric UTL is simply the maximum blank concentration. However, the coverage for non-parametric UTLs is a function of the sample size and must be calculated instead of specified. It is often less than the coverage of 95% used for the normal UTLs because more than 59 samples are required before the maximum measurement is expected to equal or exceed the 95th percentile. Log-normal UTLs are not preferred for this approach because often too little data is available to be confident that the sample distribution is truly log-normal and thus what appear to be extremely high UTLs cannot be adequately defended.

Sample results are compared to the appropriate blank UTL (by analyte, analytical method, matrix, year, etc.). Any sample result greater than its blank UTL is then considered to be a significant and indicates the potential for site contamination. Sample results less than the blank UTL are concluded to be no different from analytical system noise.

This blank UTL approach is within the intent of the RAGS guidance, as suggested by the excerpts above. It provides a probabilistic cut-off value that will discriminate between individual measurements that are no different from analytical system noise and measurements that indicate potential site contamination. Using the UTL is generally a more conservative approach than the 5x/10x rule of thumb because it estimates a limit that is the 95th percentile instead of the maximum blank measurement possible from the analytical system, and it is certainly more reproducible and defensible. The blank UTL is

more justifiable because it is a more accurate assessment of the likelihood of a measurement being analytical noise or representative of site conditions. Using blank UTLs can also provide more protection against false positive (type I) errors. The intent of the five and 10 factors in the 5x/10x rule is to allow for concentrations that might exist in blanks, but that weren't seen because of the limited number of blanks available. The UTL is a statistical approach to doing exactly the same procedure. However, it takes into account how many blanks were used to make the estimate. Clearly, using the 5x/10x rule can raise the "cutoff" by collecting more blanks, since this gives a higher probability of seeing more extreme values (high results) and then the highest value is always multiplied by the 5x or 10x factor. Using UTLs, the factor decreases with larger sample sizes, reflecting the greater amount of information that you have, and therefore the decreased uncertainty in the estimate of the 95th percentile. Thus, the calculated UTLs for blank results do accomplish the USEPA's objective since the blank UTLs are probabilistic upper limits for the blank concentrations for a specific analyte.

The only disadvantage to the UTL approach is that it requires slightly more effort to look up the appropriate tolerance (e.g., K) factor and to first calculate the mean and standard deviation of the blank data. However, most statistical software packages available will do the lookup and the calculation of means and standard deviations with minimal instruction. And, although the blank UTLs may take slightly more effort to calculate, the benefits of using such an approach for blank comparisons far outweigh any additional work.

This approach has been used and accepted on several USEPA regulated environmental investigations. Since 1993, blank UTLs have been used for blank comparisons and accepted by USEPA Region X and the State of Alaska for several projects. It is proposed that this approach be used in all cases where it is necessary to determine if a site result may be due to analytical system noise. The details to implementing this approach will vary by project. Details for implementing this approach for a study with data collected over several years for several matrices is provided below.

3.0 PROPOSED IMPLEMENTATION OF THE UTL APPROACH

One of the first crucial steps in determining if a site result is due to analytical system noise, no matter if the 5x/10x or UTL or some other approach is used, is to determine which blank sample results characterize the analytical system in question and to evaluate these for outlier data points. Outlier data points indicate that some anomalous situation occurred which should not be included in a characterization of the system noise. Box plots of the data should be generated for each type of blank data and for each matrix (waters and soils). Box plots are useful graphical tools for comparing the central tendency and dispersion of data distributions. Additionally, an outlier test can be built into the drawing of the box plots so that outliers are depicted on the plots. The statistical software package SAS performs an outlier test and generates box plots as part of one of its summary statistics procedures (SAS, Proc Univariate).

For a given analyte, these box plots will show, in general, whether there are any apparent differences among the distributions of blank results for the different types of blanks (e.g., ambient, equipment, method, trip, etc.). The primary reason for combining types of blank data is to understand the overall uncertainty due to sampling procedures and equipment, analytical procedures and equipment, etc. The overall uncertainty also includes the batch-to-batch variability that is so often missed when decisions are made on the basis of one method blank result. Outliers and other anomalies are investigated and appropriate corrective action taken. Blank data would not be combined across the various years of sampling because each year has different sampling objectives, sampling teams, and possibly even different sampling equipment and analytical laboratory and procedures. However, it is appropriate to combine blank data types within one sampling/analytical event because the sources of "noise" will be consistent and persistent for that event. If no apparent differences exist between the types of blank data, then the different types of blank results can be pooled together for each matrix and analyte (and year or other category). If any apparent differences do exist, then the blank data can not be pooled together and it must be

determined which blank data best characterize the analytical system that generated the site-sample results.

In detail, the procedure for estimating and using blank UTLs for blank comparisons is:

- (1) to compare data from all types of blanks,
- (2) to combine or to determine the most representative blanks,
- (3) to calculate a UTL with appropriate blank data considering the distributional characteristics of the sample data,
- (4) to compare individual site results to their respective UTL and to conclude sample results greater than the UTL are different from the analytical noise.

Analytical Method	Analyte	Units	N	Minimum	Maximum	Freq of Occ.(1)	UTL for Blank Data(2)	Chemical of Potential Concern?	Footnote
SH8240	trans-1,2-Dichloroethene	mg/kg	6	ND	ND	0.0	NC	No	e
SH8240	trans-1,3-Dichloropropene	mg/kg	6	ND	ND	0.0	NC	No	a

N = 128

ND = Not detected.

NC = Not calculated. UCL cannot be calculated with only one site result.

a. Random uniform numbers between zero and the minimum result substituted for non-detected values.

b. One-sided 95% upper confidence limit for the mean.

a. No measureable results on site.

b. Average metal concentration on site significantly greater than

average background metal concentration ($\alpha = 0.20$).

c. Average metal concentration on site not significantly greater than

average background metal concentration ($\alpha = 0.20$).

d. Frequency of occurrence $\geq 5\%$.

e. Frequency of occurrence $< 5\%$.

f. No UTL for blanks not calculated and frequency of measureable results $\geq 5\%$.

g. No UTL for blanks not calculated and frequency of measureable results $< 5\%$.

Parameters used in this report:										
Body weight, adult		70.00000 kg							0.50000	
Body weight, child		15.00000 kg							0.00000	g/cm ³
Lifetime		70 years							6.00000	years
Exposure Duration		6 years							50000000.00	cm ²
Exposure Frequency		350 days/year							0.00000	m
Exposure Interval		0.00	sec.						0.00000	m
Absorption Factor		1.00000							0.00000	m ³ /day
Soil Intake Assumption, adult		0.10000	g/day						0.00000	m/sec
Soil Intake Assumption, child		0.20000	g/day						4.50000	m/sec
Age-adjusted Soil Ingestion Factor		114.29000	mg-yr/kg-day						12.80000	m/sec
Cancer Risk, Class A,B		.00000100							0.00000	
Cancer Risk, Class C		.00000100							0.04970	
Hazard Quotient		1.00000							0.10000

Table B-2
(Continued)

Parameters used in this report:			
Body weight, adult	70.00000	kg	
Body weight, child	15.00000	kg	
Lifetime	70	years	
Exposure Duration	6	years	
Exposure Frequency	350	days/year	
Exposure Interval	0.00	sec.	
Absorption Factor	1.00000		
Soil Intake Assumption, adult	0.10000	g/day	
Soil Intake Assumption, child	0.20000	g/day	
Age-adjusted Soil Ingestion Factor	114.29000	mg-yr/kg-day	
Cancer Risk, Class A,B	.00000100		
Cancer Risk, Class C	.00000100		
Hazard Quotient	1.00000		
True Soil Porosity	0.50000		
True Soil/Particulate Density	0.00000	g/cm ³	
Averaging Time	6.00000	years	
Area of Contamination	50000000.00	cm ²	
Side Length of Contaminated Area	0.00000	m	
Diffusion Height	0.00000	m	
Inhalation Rate	0.00000	m ³ /day	
Wind Speed	0.00000	m/sec	
Mean Annual Wind Speed	4.50000	m/sec	
Equivalent Threshold Wind Speed	12.80000	m/sec	
Vegetative Cover	0.00000		
Um/Ut Function	0.04970		
Decision Factor	0.10000

Table B-17
(Continued)

Parameters used in this report:

Body weight, adult	70.00000	kg
Body weight, child	15.00000	kg
Lifetime	70 years	
Exposure Duration	6 years	
Exposure Frequency	350 days/year	
Exposure Interval	0.00	sec.
Absorption Factor	1.00000	
Soil Intake Assumption, adult	0.10000	g/day
Soil Intake Assumption, child	0.20000	g/day
Age-adjusted Soil Ingestion Factor	114.29000	mg-yr/kg-day
Cancer Risk, Class A,B	.00000100	
Cancer Risk, Class C	.00000100	
Hazard Quotient	1.00000	

True Soil Porosity	0.50000	
True Soil/Particulate Density	0.00000	g/cm ³
Averaging Time	6.00000	years
Area of Contamination	50000000.00	cm ²
Side Length of Contaminated Area	0.00000	m
Diffusion Height	0.00000	m
Inhalation Rate	0.00000	m ³ /day
Wind Speed	0.00000	m/sec
Mean Annual Wind Speed	4.50000	m/sec
Equivalent Threshold Wind Speed	12.80000	m/sec
Vegetative Cover	0.00000	
Um/Ut Function	0.04970	
Decision Factor	0.10000

Table B-27
Comparison of POL Tank Farm Maximum Daily Intake for
Essential Nutrients to Recommended Daily Allowances (RDA)

Nutrients	Maximum Detected Concentration at the Site		RDA ^a mg/day	Calculated Maximum Daily Intake	
	Water mg/L	Soil mg/kg		Water ^b mg/day	Soil ^c mg/day
Iron	120	NA	10	240 ^d	NA
Selenium	NA	0.85	0.07/0.055	NA	1.7E-04

^a Source: Recommended Dietary Allowances, 10th Edition, National Research Council, Washington, DC, 1989.

^b Assumes intake of 2 liter/day of water having the maximum detected concentrations.

^c Assumes intake of 200 mg/day of soil having the maximum detected concentrations.

^d The maximum daily intake for iron in water exceeded the RDA.

Table B-28
Comparison of West Unit Maximum Daily Intake for
Essential Nutrients to Recommended Daily Allowances (RDA)

Nutrients	Maximum Detected Concentration at the Site ^a		RDA ^b mg/day	Calculated Maximum Daily Intake	
	Water mg/L	Soil mg/kg		Water ^c mg/day	Soil ^d mg/day
Calcium	260	15,000	800	520	3.0
Iron	150	31000	10	300 ^e	6.2
Magnesium	43	7800	350	86	1.56
Potassium	5.9	1200	2000	11.8	0.24
Sodium	69.4	320	500	138.8	0.064
Copper	NA	260	3	NA	0.052
Selenium	1.01	2.2	0.07/0.055	0.014	4.4E-04
Zinc	0.05	1100	15	0.0966	0.22

^a Concentration listed is the maximum detected concentration at any of the sources in the west unit.

^b Source: Recommended Dietary Allowances, 10th Edition, National Research Council, Washington, DC, 1989.

^c Assumes intake of 2 liter/day of water having the maximum detected concentrations.

^d Assumes intake of 200 mg/day of soil having the maximum detected concentrations.

^e The Maximum Daily Intake for iron in water exceeded the RDA in JP-4 Fillstands and Million Gallon Hill source areas.
